Systemic inflammation caused by chronic periodontitis in acute ischemic heart attack patients

Inflamação sistêmica causada pela periodontite crônica em pacientes vítimas de ataque cardíaco isquêmico agudo

Abstract

Objective: Infectious and inflammatory processes mediated by bacteria in distant sites have been described as a risk factor for acute ischemic heart disease (AIHD).

Methods: One hundred one patients with AIHD with and without chronic periodontitis (CP) were included in this study. Patients were admitted to the HC Unicamp and stratified into three groups: in group 1, we selected patients with severe chronic periodontitis (31 men and 19 women, mean age 55.1 ± 11.29 years old); the group 2 with mild chronic periodontitis (40 men and 28 women, mean age 54.8 ± 10.37 years old) and group 3 represented by the toothless (43 men and 20 women, mean age 67.5 ± 8.55 years old). Blood samples were collected to measure the lipid profiles, hematological and blood glucose levels. In addition, biopsies of seventeen coronary arteries with atherosclerosis and an equal number of internal mammary arteries without atherosclerotic degeneration in group 1 were investigated. Statistical analysis by analysis of variance (ANOVA) and Scheffé test for multiple comparisons was performed.

Results: Triglyceride and LDL levels were elevated in group 1 than in group 2. HDL were reduced by 20% in group 1 and remained reduced by 8% in toothless. Blood glucose was higher in group 1. DNA of periodontal bacteria was detected in 58.8% of the coronary arteries.

Conclusions: Patients with (AIHD) and severe chronic periodontitis may have altered lipid profile, as well as microorganisms associated with CP can permeate into coronary vessels.

INTRODUCTION

The chronic periodontitis presents as chronic infectious diseases characterized by inflammatory changes in periodontal tissues. These are mainly caused by gram-negative bacteria, including Porphyromonas gingivalis (Pg), Prevotella intermedia (Pi), Aggregatibacter actinomycetemcomitans (Aa) and Tannerella forsythia (Tf) [1].

Chronic bacterial infections caused by Chlamydia pneumoniae and chronic periodontitis, as well as certain viruses have been associated with risk for systemic conditions such as coronary artery disease and atherosclerosis [2]. Species associated with chronic periodontitis can enter the blood flow through gingival blood vessels and migrate to the atheromatous plaques [3].

Traditional risk factors and well-established coronary diseases, including hypertension, diabetes, obesity, smoking and physical inactivity does not fill half of the cases affected with this disease [4].

Hypercholesterolemia, specially high levels of low density lipoproteins (LDL-C), hypertriglyceridemia and low levels of high density lipoprotein (HDL-C) are major risk factors for acute coronary syndromes [5].

The basis of this study was to observe patients presenting with acute ischemic heart disease with and without chronic periodontitis, the behavior of the lipid, hematological and blood biochemical profile as well as assessing biopsies of internal mammary and coronary arteries to detect the presence of Chlamydia pneumoniae and bacteria related to chronic periodontitis.

METHODS

Sample

One hundred and eighty-one patients with acute ischemic heart disease, diagnosed by electrocardiography and/or angiography as well as clinically and biochemically (CK, CK) are included in this study. All patients were informed verbally and in writing to participate in the research, and the study was approved by the Research Ethics Committee of the Faculty of Medical Sciences at UNICAMP. The periodontal examinations were performed within the first 24 hours, from admission at coronary care unit of HC/ UNICAMP. Of the total patients, 63 are toothless as gender distribution, mean age and standard deviation (43 men and 20 women, mean age 67.5 ± 8.55 years). The remaining 118 patients were subdivided into

Resumo

Objetivo: Processos inflamatórios e infecciosos mediados por bactérias em sítios distantes têm sido descritos como fator de risco à doença coronariana isquêmica aguda (DCIA).

Métodos: Cento e oitenta e um pacientes com DCIA, com e sem periodontites crônicas, foram incluídos neste estudo. Os pacientes foram admitidos no HC da UNICAMP e estratificados em três grupos: grupo 1 - pacientes com periodontite crônica grave (31 homens e 19 mulheres; média de idade 55,1 ± 11,29 anos); grupo 2 - pacientes com periodontite crônica leve (40 homens e 28 mulheres; média de idade 54,8 ± 10,37 anos); grupo 3 - pacientes desdentados (43 homens e 20 mulheres; média de idade 67,5 ± 8,55 anos). Amostras sanguíneas foram coletadas para mensurar os perfis lipídico, hematológico e glicêmico. Além disso, biópsias de 17 artérias coronárias com aterosclerose e igual número de artérias mamárias internas sem degeneração aterosclerótica no grupo 1 foram investigadas. Para análise estatística utilizou-se a análise de variância (ANOVA) e o teste de Scheffé para comparações múltiplas.

Resultados: Triglicérides e LDL estavam elevados no grupo 1 em relação ao grupo 2. O HDL apresentou-se reduzido em 20% dos pacientes do grupo 1, e em 8% nos desdentados. A glicemia estava elevada no grupo 1. DNA de bactérias periodontais foram detectados em 58,8% das artérias coronárias.

Conclusões: Pacientes com DCIA e periodontite crônica grave podem apresentar perfil lipídico alterado, como também microorganismos associados com as periodontites crônicas graves podem permar dentro de vasos coronarianos.

two subgroups: fifty presented severe chronic periodontitis (31 men and 19 women, mean age 55.1 ± 11.29 years), with more than 30% of teeth affected with loss of periodontal clinical attachment level > 4 mm, with more than five periodontal pockets with probing depth > 5 mm and presenting at least 20 dental units) and the other with mild chronic periodontitis (40 men and 28 women, mean age 54.8 ± 10.37 years), with less than 30% of teeth affected with loss of clinical attachment level < 3 mm and without periodontal pockets, as well as 20 dental units. This classification of mild and severe chronic periodontitis is accoding with consensus on chronic periodontitis of the American Academy of Periodontology [6].

Samples of 17 coronary arteries with atherosclerosis and same number of internal mammary artery (used as grafts) with no atherosclerotic degeneration were investigated for detection of periodontal pathogens and Chlamydia pneumoniae. Fragments of specimens of coronary and mammary artery were obtained during surgery for coronary artery bypass grafting, and were removed from the site of the anastomosis in the coronary arteries and distal segments of mammary grafts during its preparation. These patients were followed-up by the Cardiac Surgery and Cardiology Discipline Department at Clinics Hospital of the Faculty of Medical Sciences, State University of Campinas (HC-UNICAMP). All arterial specimens were obtained from the same group of patients with severe chronic periodontitis.

Immediately after the biopsy, the arterial specimens were frozen in nitrogen and stored at -80°C. The detection of pathogens was performed by analysis of polymerase chain reaction (PCR).

**PCR and DNA extraction**

Vessels removed were treated with proteinase K at 56°C for 30 minutes followed by 10 minutes of proteinase K inactivated at 95°C, and with 5 minutes centrifugation in a microcentrifuge to remove cellular debris. PCR was performed in volumes of 25 µl containing PCR/Mg++ buffer, 0.2 µM of deoxyctosine tripophosphate (dCTP), deoxyguanosine tripophosphate (dGTP), deoxadenosine tripophosphate (dATP), and deoxythymidine triphosphate (dTTP), 0.2 µM of each primer, 0.5 U Taq DNA polymerase, and 3-5 µl template DNA containing supernatants. The amplification was performed in a DNA thermal cycler programmed to 94°C (5 minutes), followed by 35 cycles at 94°C (30 seconds), annealing temperature appropriate for each primer pair (30 seconds) and extension at 72°C (1 minute and 30 seconds), plus a final extension at 72°C (5 minutes). The PCR amplified fragments were visualized on polyacrylamide gel at 8%, stained with ethidium bromide on UV transilluminator. The primers used in the study include: Universal primer *Escherichia coli* 16S rDNA (pF1: 5 AGA GTT TGA TCC TGG CTC CAG 3) (*E. coli* - position: 28-27), *Aa* (Aa1: 5 CAC TTA AAG GTC CGC ATA CGT GC 3) *C. pneumonia* (HL-1-GTT GTT CAT GAA GGC CCT ACT HR-1-TGC ATA ACC TAC GGT TGT GTT) *Pg* (Pg1: 5 CAA TAC TCG TAT CGC CGG TTA TTC 3) *Pi* (Pi: 5 GTT GGC TGC ACT CAA GTT CGC C 3), *Tf* (TF V530: 5 GTA GAG CTT ACA CTA TAT CGG AAA CTC GTA 3).

**American Type Culture Collection (ATCC) cultures of** *Pg* (ATCC 33277), *Aa* (ATCC 33 384), *Tf* (ATCC 43 037) and *Pi* (ATCC 25 611) were used as positive control. The negative control was a PCR mix without DNA.

**Medical History**

Demographic features, individual habits and cause of loss of teeth units in toothless were also observed. Patients in the study showed no other cardiac or infectious disease, and were not taking any medication or antibiotic drugs that could reduce cholesterol levels, as well as not having undergone any periodontal treatment in the last six months.

**Laboratory analysis**

When admitted to the coronary care unit, all patients in the study underwent fasting blood sample for diagnosis of lipid, glycemic and haematological profile. All examinations were performed in the clinical pathology laboratory of the hospital.

The following limit values for lipids and lipoproteins, according to the National Cholesterol Education Program - Adult Treatment Panel III (NCEP-ATP III) [11] were considered: total cholesterol (TC): desirable <200 mg/dL, borderline risk 200-239 mg / dl and high 240 mg/dl. Triglycerides (TG): normal <150 mg/dl borderline 150-199 mg / dl, high 200-499 mg/dl and very high 500 mg/dl. HDL: low <40 mg/dl; high 60 mg/dl. LDL: optimal <100 mg/dl and above optimal 100-129 mg/dl; limit of the high 130-159 mg/ dl, high 160-189 mg/dl and very high 190 mg/dl.

Fasting glucose and white cell count had the limits: ≤ 110 mg/dl and 4000-10000 mm³, respectively.

**Periodontal Examinations**

The patients were periodontally examined by a single examiner, using a mouth mirror, direct lighting and manual probe PCP-UNC 15 in the hospital bed. The PCP-UNC 15 probe was used to detect the level of clinical attachment and periodontal pocket depth and is expressed as the distance in millimeters from the cemento-enamel junction in the dental unit and gingival margin at the bottom of the gingival pocket. These parameters were measured at six sites per tooth (mesiobuccal, mid-buccal, disto-vestibular, mesiolingual, mid-lingual and distal-lingual) in the contralateral superior and inferior quadrants, with a threshold of loss of clinical attachment level greater than 4 mm and > 5 mm in the periodontal pockets, being considered
affected by severe chronic periodontitis and also presenting at least 20 dental units.

The patients’ age and the variables that compose the lipid profile, as well as white cell counts were described by mean and standard deviation.

**Statistical analysis**

The hypothesis of equality between these means in the three groups was tested by analysis of variance (ANOVA). Comparisons between each possible pair of means were assessed using the Scheffé test [7], considering statistically significant the differences between means whose P value was less than 5%. All these data were assessed using the software STAT-VIEW 5.0 (SAS Institute Inc., Cary, NC, USA).

**RESULTS**

The study was performed from November 2000 to May 2005 when we selected 181 patients with acute ischemic coronary disease, by chronological addition at HC/UNICAMP, according to the inclusion criteria specified.

Figures 1-3 show the groups with and without chronic periodontitis and traditional risk factors of acute ischemic heart disease.

Age is a factor all with high prevalence in the incidence of tooth loss, with statistically significant differences between groups with chronic periodontitis and toothless, but no statistical significance between those with mild and severe chronic periodontitis.

The body mass index was equivalent in all three groups, according to the classification of obesity in adults from the World Health Organization [8].

It was observed prevalence of male gender, white race and hypertension, on which these percentages were above 70% on average in the three groups.

Family history of hypertension and cardiovascular diseases have not reached the percentage of 50% on average in the three groups.

The incidence of diabetes in both groups was around 20% with higher prevalence in the group with severe chronic periodontitis in approximate percentage of 37%.

Figure 4 shows the means and standard deviations in groups of lipid and glycemic profiles. Although no statistically significant differences between groups in lipoproteins (HDL-C, LDL-c) were found, we observed reduced values of the limit of HDL-cholesterol that could be considered low, with a drop more pronounced in the group with severe chronic periodontitis in approximately 20% as well as 8% in the toothless group.

Moreover, LDL-cholesterol was above the normal range and therefore away from the value considered optimal, in approximately 20% in patients with severe chronic periodontitis and 15% in toothless patients, but with normal values in the group with mild chronic periodontitis.

Triglycerides and total cholesterol were high in about 53% and 27% respectively in the group with severe chronic
periodontitis in relation to the group with mild chronic periodontitis. However, these lipids (triglycerides and total cholesterol) were similar between the groups with severe chronic periodontitis and the toothless group.

Triglycerides and LDL-cholesterol levels were approximately 13% and 20% above the limit values in the groups with severe chronic periodontitis and toothless group, while total cholesterol was in normal levels in the three groups.

Blood glucose was high in approximately 20% of the limit in the group with severe chronic periodontitis, but with normal values in other groups.

The white cell count was more high in the group with severe chronic periodontitis in approximately 43%, while in groups with mild chronic periodontitis and toothless were high in 20% (Figure 5).

DNA from periodontal bacteria were detected in samples from the coronary artery in the following proportions: Porphyromonas gingivalis (52.9%), Aggregatibacter actinomycetemcomitans in six (35.3%) biopsies, Prevotella intermedia in four (23.5%), and Tannerella forsythia in two (11.7%) samples. Seven (41.1%) specimens were positive for two or more periodontal bacteria. The association between Porphyromonas gingivalis and Aggregatibacter actinomycetemcomitans was found in ten of the 17 arteries studied (Figure 6).

Periodontal pathogens were not detected in internal mammary arteries. Chlamydia pneumonia was detected in six (35.3%) internal mammary arteries and coronary. Mixed infection with Chlamydia and periodontal pathogen was observed in four specimens of the coronary artery (Figure 6).

DISCUSSION

Several studies have shown an association between chronic periodontitis and levels of serum lipoproteins, but with some controversy between them. Studies suggest that there is a relationship between levels of total cholesterol and periodontitis [9,10], while other researchers have found a relationship between triglyceride levels and periodontitis [11,12]. However, another group of researchers found that chronic periodontitis were associated with high levels of
total cholesterol and triglycerides [13], demonstrating a similar relationship with our research.

In our study total cholesterol level was normal in all three groups, but was higher in the group with severe chronic periodontitis, a fact confirmed by other researchers [11,13].

More recently, Monteiro et al. [14] has shown that in individuals without coronary disease but with severe chronic periodontitis, the levels of triglycerides were high, while HDL cholesterol proved to be reduced, citing similarities with this study.

Using an animal model of chronic periodontitis-induced, some investigators have detected increased levels of LDL cholesterol in the peripheral level [15]. In the same direction, levels of LDL-cholesterol presented higher when compared to the severity of chronic periodontitis in our sample.

High concentrations of LDL-cholesterol and triglycerides and low levels of HDL cholesterol are well established as risk factors for coronary heart disease.

Patients who presented severe chronic periodontitis in our sample, and several clinical periodontal parameters in other studies showed high levels of triglycerides [16].

Specific bacteria that cause severe chronic periodontitis induce a response in the host, with the production and release of pro-inflammatory cytokines in gingival tissues, which flow into the blood flow, triggering a hepatic response of the liver, thereby raising levels of acute-phase proteins, mainly C-reactive protein [17].

Patients with poor glycemic control is widely known as a risk factor for severe chronic periodontitis [20], as well as chronic periodontitis in its various forms can deteriorate glycemic control [21], a fact observed in our sample.

The white cell count (Figure 5) represents a recent indicator of risk for coronary heart disease. This biochemical finding may be associated with unidentified infectious processes (chronic oral infections), which in our sample is higher in those with severe chronic periodontitis [22].

Studies in animal experiment demonstrated that intravenous administration of bacteria that cause chronic periodontitis increases the formation and calcification of atheromatous plaques [23].

Haraszthy et al. [3] examining 50 biopsies of aortic arteries with atheromas and using molecular biology techniques, found that 22 (44%) arteries were positive for several periodontal bacteria, including Tanneraella forsythia in 30%, Porphyromonas gingivalis in 26%, Prevotella intermedia in 14% and Aggregatibacter actinomycetemcomitans in 18%, thus showing similarity with our sample.

In another study using molecular biology techniques [24], the researchers detected Aggregatibacter actinomycetemcomitans and Prevotella intermedia in approximately 31% of multiple arterial specimens. In our sample, seventeen of coronary arteries with atherosclerosis studied, one-third (33%) had both periodontal bacteria.

Zaremba et al. [25], using 20 patients who underwent surgery for coronary artery patency and presenting diagnosis of severe chronic periodontitis, 13 periodontal bacteria were detected in obstructed coronary vessels. The authors noted that 10 of the 20 patients presented the same bacterial clones from periodontal pockets and in the coronary vessels.

Using the polymerase chain reaction, Aimetti et al. [26] found 33 external carotid atheromas to research of five species of bacteria that induce severe chronic periodontitis, in which the bacteria most prevalent (nearly 70%) was the Tanneraella forsythia, contrasting with our findings (12%).

Comparing the presence of periodontal bacteria in gingival pockets in patients with various levels of involvement of coronary arteries, Gotsman et al. [27] detected a higher prevalence of Porphyromonas gingivalis in those with a greater number of vessels affected. In this direction, Stein et al. [28] detected using hybridization techniques, the prevalence of Porphyromonas gingivalis in gingival pockets, in patients with acute myocardial infarction in comparison to their respective healthy controls.

However, in case-control study [29], the researchers found a higher prevalence of Prevotella intermedia when comparing patients evaluated for coronary artery disease and their respective healthy controls.

Zhang et al. [30], using animal models and inoculating once a week for four, eight and twelve consecutive weeks the Porphyromonas gingivalis in iliac arteries, they observed that the animals developed inflammation of the arterial intima and increases in other blood biochemical parameters related to inflammation throughout the study.

In our study, we detected the presence of pathogenic bacterial DNA that induces severe chronic periodontitis in about 60% of the coronary arteries studied. Porphyromonas gingivalis was the periodontal pathogen most frequently detected (Figure 6). All specimens of internal mammary arteries were negative for the bacteria that cause severe chronic periodontitis.
Internal mammary artery is considered a vessel protected from the atherosclerotic process, thus being an ideal graft for the bridge and free from infection caused by periodontal microorganisms, in contrast to infections caused by *Chlamydia pneumoniae* (35.29%).

The rate of detection of *Chlamydia pneumoniae* in our sample was 29.41% in the coronary artery, while in other studies the detection rate was around 40% [31], thus showing similar data with our study.

Based on these data, the hypothesis that the bacteria associated with severe chronic periodontitis can penetrate the ulcerated gingival epithelium, with access to blood flow and lodge in atheromatous plaques, as well as if these infections may alter the lipid profile in patients who suffered ischemic heart attack.

Therefore, further studies are needed to elucidate this relationship with large number of patients by means of longitudinal studies, and note mainly the frequency and incidence of microorganisms associated with gingival disease in periodontal pockets and in atheromatous plaques of patients with acute ischemic heart disease.
